CASE REPORT

Abstract— NPWT is increasingly used in patients with diabetic foot. The protocol for performing NPWT is subject to debate. Main concerns regard the type of suction to use (continuous, intermittent, or variable), the wound-packing material, or the exact pressure to apply. Typically, an optimum pressure range of ~80 to ~125 mmHg is indicated. Following bone resection in diabetic foot patients, the surgical wound is left open, which often entails bleeding from the resection site. In these cases, the start of NPWT was typically delayed by 24–48 hours – during that time a pressure dressing was applied – and NPWT was only started once bleeding had ceased. In order to initiate NPWT as soon as possible, we decided to start it at a higher negative pressure than usual, i.e. ~180 mmHg, expecting that this would stop the bleeding. Only then would we reduce the negative pressure. This paper presents the course of NPWT with high negative pressure values after an amputation in 2 diabetic foot patients. In both cases, our assumptions were confirmed. The patients did not bleed, the drained volume did not exceed 30 ml (which seems clinically insignificant) in the first 40 minutes of treatment. Later, with negative pressure at ~120 mmHg, no bleeding into the dressing was observed. Following the treatment (which lasted for 9 days), the wounds granulated normally, with no signs of inflammation. Applying VAC dressing using high negative pressure values to bleeding wounds immediately after surgery may stop the bleeding, enabling immediate initiation of NPWT.

Keywords—negative pressure wound therapy, diabetic foot, amputation, bleeding

I. INTRODUCTION

NEGATIVE pressure wound therapy (NPWT) is increasingly used in patients with diabetic foot, both in treating wounds caused by ulceration, and in healing surgical wounds following bone resection. NPWT assists in wound healing in a number of ways: it drains exudate, contracts the wound edges, alters blood flow in the wound edges, stimulates angiogenesis, reduces tissue edema, stimulates the formation of granulation tissue, creates a moist environment, and stimulates the wound bed. Multiple studies indicate that NPWT is superior to other wound dressing methods in the treatment of diabetic foot. The protocol for performing NPWT is subject to debate. Indications for when NPWT should and should not be used have been established quite clearly. However, indications regarding the type of suction to use (continuous, intermittent, or variable), the wound-packing material, or the exact pressure to apply are less definitive. Typically, an optimum pressure range of ~80 to ~125 mmHg is indicated, though other recommendations can also be found: Timmers et al. (2005) suggest, for instance, that the best wound healing outcomes can be achieved at pressures ranging from ~250 to ~300 mmHg. Following bone resection in diabetic foot patients, the surgical wound is left open, which often entails bleeding from the resection site. In these cases, the start of NPWT was typically delayed by 24–48 hours – during that time a pressure dressing was applied – and NPWT was only started once bleeding had ceased. This was due to the widespread belief that applying NPWT immediately after the surgery might increase bleeding. However, in order to initiate NPWT as soon as possible, we decided to start it at a higher negative pressure than usual, i.e. ~180 mmHg, expecting that this would stop the bleeding. Only after achieving hemostasis would we reduce the negative pressure. This paper presents the course of NPWT with high negative pressure values after an amputation in 2 diabetic foot patients.

II. CASE REPORT

A. Surgical interventions

Patient A (53 years old), suffering from type-2 diabetes, hypertension, and coronary artery disease, was referred to our hospital with necrosis of the fourth toe and extensive phlegmon of the right foot. Initial debridement of the wound was performed on an outpatient basis: an amputation of the forefoot tissue was initiated (Fig. 1). Subsequently, the patient was admitted to our hospital for further diagnostics and therapy. A blood culture test was run and a targeted antibiotic therapy was initiated (Ciprofloxacin 2 x 400 mg i.v.). After 4 days of conservative treatment, clinical symptoms of ischemia in the distal parts of the limb were found. Therefore a computed tomography angiography of lower limbs was...
performed. A critical constriction of the superficial femoralartery of the left limb was discovered. A vascular recon-
structive surgery was performed – reversed femoral-popliteal saphenous vein bypass. A proper blood supply was obtained, which was confirmed by a Doppler ultrasonography. In the first week post-operatively, an inflammatory progression occurred in the distal part of the limb. Extensive necrosis developed in the fifth toe and part of the subcutaneous tissue of the forefoot and sole. The patient underwent non-
anatomical amputation of the fifth toe, and resection of the fourth and fifth metatarsophalangeal joints together with the distal parts of the fourth and fifth metatarsal bones (Fig. 2). A broad-spectrum antibiotic therapy was initiated (Tazocin 3 x 4.5g i.v.). Throughout the entire hospital stay the patient continued insulin therapy (Insulatard: 16 u – 0 u – 28 u; NovoRapid: 16 u – 10 u – 8 u) and Clexane was administered subcutaneously (1 x 40 mg).

Patient B (55 years old), suffering from Charcot foot and diabetic foot ulcer, previously managed on an outpatient ba-
sis, was admitted to our hospital with extensive phlegmon in the left crus and foot. Crural amputation was performed, with standard suturing of the stump. Despite targeted antibiotic treatment (Imipenem 500 mg/Cilastatin 500 mg x 4 i.v.), 3 days post-operatively massive phlegmon developed in the stump tissues, with inflammatory infiltration of the soft tissue of the thigh. Surgical wound revision was performed, which involved removing sutures from the skin and muscle, and dissecting the skin and subcutaneous tissue from the lateral part of the thigh along the inflammatory infiltrate. Pus was evacuated, and infected and necrotic tissue was removed (Fig. 3). Throughout the entire hospital stay the patient continued insulin therapy (Humulin N: 16 u – 0 u – 14 u; Humalog 14 u – 12 u – 10 u) and Clexane was administered subcutaneously (1 x 100 mg).
BIAŁECKI et al.: APPLYING NPWT TO BLEEDING OPEN WOUNDS AFTER FOREFOOT AMPUTATION

Figure 4. Foot after fourth and fifth metatarsal bone amputation, with the VAC dressing applied immediately after the procedure.

B. NPWT treatment

In both cases, despite parenchymatous bleeding from the surrounding tissue, a VAC dressing (Renasys-F, Ontario, Canada) was applied immediately after the surgery. A polyurethane foam dressing was cut to fit the wound (Fig. 4). The dressing was sealed and NPWT was started. A pressure of −180 mmHg was applied for the first 30 minutes after the procedure, then −140 mmHg for the next 10 minutes. Subsequently, the negative pressure was reduced to −120 mmHg and maintained until the end of treatment.

In both cases, our assumptions were confirmed. The patients did not bleed, the drained volume did not exceed 30 ml (which seems clinically insignificant) in the first 40 minutes of treatment. Treatment continued for 3 days, after which the dressing was changed. Then, NPWT was continued for the next two 3-day cycles, with the dressing changed again on the 6th post-operative day. Throughout the entire 9-day treatment the wound did not bleed. The VAC dressing drained a mean volume of 40 ml of serosanguineous exudate per day. Following the treatment, the wounds granulated normally, with no signs of inflammation (Fig. 5).

III. DISCUSSION

NPWT is now commonly used in the treatment of diabetic foot. Though general indications for the treatment have been established, no single protocol has been developed. Reports from a number of centers indicate that in cases of open wounds following amputation or bone resection in patients with diabetic foot, early start of NPWT may trigger or exacerbate bleeding. Hence, treatment start was typically delayed by 24–48 hours, until after hemostasis had been achieved. This is also the protocol recommended by some authors.19–20

The standard method for the achievement of hemostasis is electrocoagulation. However, in cases of diabetic foot, this creates multiple new thermal necrosis sites, which is undesirable, particularly if infection exists. Another method for managing bleeding from the surgical wound involves applying a pressure dressing, which restricts blood flow to the tissues. However, this delays the start of NPWT, while the larger volume of secretions remaining in the wound increases treatment time. If the tissues surrounding the wound are infected, it is desirable to apply NPWT as soon as possible, which allows for early drainage of the secretions that inhibit wound healing due to the content of proinflammatory factors. To effectively remove the secretions from the wound, we decided to apply a VAC dressing onto the fresh wound, immediately after the surgery. Bearing in mind the concerns related to bleeding, we attempted to adjust the negative pressure in a way ensuring the evacuation of secretions without causing bleeding. Some studies on NPWT discuss the impact of the negative pressure in the dressing on blood supply to the surrounding tissue. (It should be noted that measurements to determine the optimum negative pressure value are performed on tissues with a specific compactness — therefore, their results should not be automatically used to prescribe pressure values for use in tissues with different properties. For instance, different pressures may be optimal for the abdominal wall and for the foot.) Wackenfors et al., studying the impact of negative pressure values ranging between −50 and −200 mmHg on microvascular blood flow around the wound in porcine models, reported that the use of NPWT may reduce microvascular blood flow in the tissues directly adjacent to the wound, and that the higher the negative pressure value, the greater the affected area.21–22
Based on this report and our own experience with NPWT, we decided to apply a negative pressure of \(-180\) mmHg for the first 30 minutes, to prevent bleeding. The negative pressure was then reduced to \(-140\) mmHg for the next 10 minutes. After that, treatment was continued at the standard pressure of \(-120\) mmHg. This allowed us to start NPWT immediately after the surgery without increasing the risk of bleeding. Further observations are required to develop a protocol for NPWT after amputations in diabetic foot patients.

IV. Conclusion
Applying VAC dressing using high negative pressure values to bleeding wounds immediately after surgery may stop the bleeding, enabling immediate initiation of NPWT. Further observations are required to develop a protocol for NPWT after amputations in diabetic foot patients.
